Abstract
Electron-impact vibrational-excitation cross sections, involving rovibrationally excited N₂ and NO molecules, are calculated for collisions occurring through the nitrogen resonant electronic state N²⁺(X²Πg), and the three resonant states of nitric oxide NO⁻(³Σ⁻, ¹Δ, ¹Σ⁺). Complete sets of cross sections have been obtained for all possible transitions involving 68 vibrational levels of N₂(X１Σ⁺g) and 55 levels of NO(X²Π), for incident electron energy between 0.1 and 10 eV. In order to study the rotational motion in the resonant processes, cross sections have also been computed for rotationally elastic transitions characterized by the rotational quantum number J running from 0 to 150. The calculations are performed within the framework of the local complex potential model, using potential energies and widths optimized to reproduce the experimental cross sections available in the literature. Rate coefficients are calculated for transitions between all vibrational levels by assuming a Maxwellian electron energy distribution function in the temperature range from 0.1 to 100 eV.

All numerical data are available at http://users.ba.cnr.it/imip/cscpal38/phys4entry/database.html

1. Introduction
Vibrational transitions, induced by electron impact in diatomic molecules, play a key role in affecting the chemistry and physics of many molecular plasmas [1]. The most efficient low-energy process, leading to molecular vibrational excitation/de-excitation, occurs through a resonant mechanism, according to which the incident electron is momentarily captured by a neutral molecule, in general vibrationally excited, with the subsequent formation of a resonant negative molecular ion. Within a given time interval, the electron can acquire all, or part, of its original kinetic energy and may escape from the molecule, giving rise correspondingly to elastic or inelastic vibrational excitations [2].

We will focus our discussion on electron-impact vibrational-excitation collisions involving N₂ and NO molecules. The interest in these species relies on their relevance, as plasma components, in several fields of scientific and technological importance: from planetary atmosphere, including environmental and spacecraft re-entry problems, to nuclear fusion and industrial plasmas [3, 4].
Resonant vibrational excitations (RVEs) for these two molecules occur via the following mechanisms:

\[ N_2(X^1\Sigma_g^+, v, J) + e \rightarrow N_2(X^2\Pi_g) \]
\[ \rightarrow N_2(X^1\Sigma_g^+, v, J) + e, \]
\[ (1) \]

\[ \text{NO}(X^2\Pi, v, J) + e \rightarrow \text{NO}^-(i^1\Sigma^-, i^1\Delta, i^1\Sigma^+) \]
\[ \rightarrow \text{NO}(X^2\Pi, v, J) + e. \]
\[ (2) \]

In both cases, the two molecules are initially in their respective ground electronic state and in one of the associated vibrational levels, labeled by the quantum number \( v \), ranging from 0 to 67 for \( N_2 \) and 54 for \( \text{NO} \) and a fixed rotational quantum number \( J \). The capture of the incident electron leads to the formation of a resonant negative ion which, after autoionization, decays back to some level \( v \) of the neutral molecule. NO contributes to process (2) with the three resonant electronic states \( 3\Sigma^- \), \( i^1\Delta \), \( i^1\Sigma^+ \), while process (1) proceeds through the resonant \( X^2\Pi \) state, responsible for the well-known 2.3 eV resonance peak in electron–\( N_2 \) collision experiments [5].

Experimental measurements [5–12] and theoretical calculations [13–20] of cross sections exist in the literature for the above processes. However, despite the broad production of cross section data, especially for nitrogen, all the previous works are restricted to excitations between the first few vibrational levels. This circumstance is particularly limiting for models of those plasma systems in which strong non-equilibrium conditions exist. In these plasma systems the vibrational distribution is no longer Boltzmann, so that the high vibrational levels can become over-populated. An appropriate example of non-equilibrium conditions is provided by the air plasma generated by the impact of a supersonic vehicle during its re-entry phase in the Earth’s atmosphere. During the air–vehicle interaction, the kinetic energy transferred to atmospheric components induces complex physical and chemical processes and may, in particular, activate the internal degrees of freedom of the molecular species whose densities can strongly deviate from a Boltzmann distribution. A realistic model, aimed at predicting the chemical and physical evolution of these plasmas, relies therefore on a detailed description of the state-to-state processes occurring at the molecular level, with particular consideration of the electron–molecule energy exchanges, whose role is of fundamental importance in determining the level population of the chemical species.

In this paper, we present complete sets of cross section data for both the excitation processes (1) and (2), connecting all the vibrational levels of \( N_2 \) and \( \text{NO} \) molecules, and for an incident electron energy interval below 10 eV. We have also extended the calculations to rotationally elastic resonant excitations of both molecules \( (J \leq 150 \text{ and } \Delta J = 0) \). The cross sections are evaluated by resorting to the local complex potential (LCP) model as formulated in [21]. The LCP approximation is derived from the more rigorous non-local model [22], which is currently the best available theory for the description of the resonant collisions. A comparison of the two models, however, reported for \( N_2 \) and \( \text{NO} \) in [15] and [18], respectively, for some transitions, shows that the results of the two methods are in good agreement, and the observed differences, although significant for testing the models, are quite inconsequential for any practical purpose. This is a favorable circumstance from a computational point of view, as the LCP model is less demanding, in terms of computer time, compared with the non-local counterpart, especially if we consider, for example, that the complete sets of vibrational data include 68 \times 68 and 55 \times 55 possible transition cross sections to be evaluated for each energy grid point. In addition to the non-negligible time-saving features, the LCP approximation also provides quite accurate results demonstrated, as shown below, by the good agreement of the calculated cross sections with the experimental measurements.

Cross sections provide the basic input data for a plasma kinetic model, from which the rate coefficients can be obtained once the electron energy distribution function, for the particular conditions of the plasma system, is known. In many situations, however, when the electrons can be considered thermalized at a given temperature \( T_e \), the rate coefficients can be obtained by convoluting the cross sections with a Maxwellian energy distribution function, according to the equation:

\[ K_{v_i \rightarrow v_f}(T_e) = \frac{8}{\sqrt{\pi}} \frac{1}{kT_e} \int_{\epsilon_{th}}^{\infty} dE E e^{-\frac{E}{kT_e}} \sigma_{v_i \rightarrow v_f}(E), \]
\[ (3) \]

where \( m_e \) is the electron mass, \( k \) is the Boltzmann constant, \( \epsilon_{th} \) is the threshold energy and \( \sigma_{v_i \rightarrow v_f}(E) \) is the cross section for the \( v_i \rightarrow v_f \) RVE for electron energy \( E \). Using the calculated cross sections for both processes (1) and (2), we have also calculated the corresponding rate coefficients, by equation (3), for all the transitions and in the range of electron temperature from 0.1 eV up to 100 eV.

The organization of the paper is as follows. In the next section we briefly describe the main equations of the LCP model and give some computational details. In section 3 we compare the calculated cross sections with some available theoretical and experimental results of the literature, and in section 4 we illustrate a few particular examples of the calculated cross sections and rate coefficients. In section 5, some conclusive comments will be provided.

2. Theoretical model and numerical details

In this section, only a brief account is given of the relevant equations of the LCP model. A comprehensive formulation of the resonant collisions can be found in [21] and references therein.

The cross section for a given rovibrational \((v_i, J_i) \rightarrow (v_f, J_f)\) transition, occurring through an electron–molecule resonant collision is given by [21]

\[ \sigma_{i\rightarrow f}(\epsilon_i) = g_i \frac{2\pi^3 m_e^2 k_i}{\hbar^2} \left| \langle \chi_i | V_{k_i} | \xi \rangle \right|^2, \]
\[ (4) \]

where \( g_i \) and \( g \) represent, respectively, the product of the degeneracy factors and spin-multiplicity of the resonant and neutral electronic states. The equation includes a multiplicative factor of 1/2 in order to account for the spin-multiplicity of the unpolarized incident electron. The initial and final electron momenta are defined by \( k_i^2 = 2m_e\epsilon_i/\hbar^2 \)
and $k^2 = 2m_e\epsilon_i/\hbar^2$, where $\epsilon_i$ and $\epsilon_f$ are the initial and the final kinetic energies of the free electron. $\chi_i = \chi_{v_i,j_i}(R)$ is the wave function of the final rovibrational state of the target molecule and $\xi(R)$ is the nuclear wave function of the resonant state, both depending on the internuclear distance $R$. The exit amplitude $V_k(R)$ is the value of the interaction matrix element, $V_k(R)$, coupling the discrete and continuum states of the colliding system [21] for the exit channel $k = k_f$.

Once the coupling matrix $V_k(R)$ and the potential energy curve of the resonant state $V^-(R)$ are known, the wave function $\xi(R)$ can be obtained in the LCP model by solving the nuclear resonant equation:

$$
\begin{aligned}
\frac{\hbar^2}{2\mu} \frac{d^2}{dR^2} + \frac{J_i(j_i + 1)\hbar^2}{2\mu R^2} + V^-(R) + \Delta(R) &- \frac{i}{2} \Gamma(R) = -V_k(R) \chi_{v_i,j_i}(R),
\end{aligned}
$$

where $\mu$ is the nuclei reduced mass and $E = \epsilon_i + E_{v_i,j_i}$ is the total energy. $E_{v_i,j_i}$ are the rovibrational eigenvalues of the target Schrödinger equation:

$$
\begin{aligned}
\frac{\hbar^2}{2\mu} \frac{d^2}{dR^2} + \frac{J_i(j_i + 1)\hbar^2}{2\mu R^2} + V_0(R) &- E_{v_i,j_i} \chi_{v_i,j_i}(R).
\end{aligned}
$$

Here $V_0(R)$ is the electronic potential energy function of the neutral molecule. In equation (5), $\Gamma(R)$ and $\Delta(R)$ are, respectively, the resonance width and the level shift, and finally, $V_k(R)$ is the entry amplitude describing the capture of the incident electron by the molecule.

The potential curves, $V^-(R)$ and $V_0(R)$, needed in equations (5) and (6), respectively, are expressed as a Morse-like function:

$$
U(R) = D_e \left[ 1 - e^{-a(R-R_c)} \right]^2 + W,
$$

where $D_e$ is the dissociation energy for the considered electronic state and $R_e$ is its equilibrium bond length. $W$ is the zero-point energy and $\alpha$ is a constant. The Morse potential parameters for the nitrogen molecule were obtained, by a fitting procedure, from the Gilmore potential [23]. The dissociation energy, measured from the potential bottom, has been taken from [24], while $\alpha$ is set in order to reproduce the first few vibrational levels of $N_2$ [25]. For NO and NO$^-$ the Morse parameters are taken from [26–28]. All the constants entering in equation (7) for the electronic states involved in processes (1) and (2) are given in table 1, along with the reduced mass, $\mu$, of $N_2$ and NO molecules. The potential curves obtained in this manner are shown in figures 1(a) and (b).

The width function $\Gamma(R)$ in equation (5) is expressed as [13]

$$
\Gamma(R) = \sum_i C_i \left[ V^-(R) - V_0(R) \right]^{l_i+1} H \left( V^- - V_0 \right),
$$

where $H$ is the Heaviside step-function and $l_i$ is the angular momentum of the lowest contributing partial wave associated with the incident electron. The sum in equation (8) runs over all the electronic states of the molecular negative ion involved in the process, which implies one term for $N_2^-$ and three for NO$^-$. For the corresponding value of the angular quantum number we have set $l_i = 2$ for the nitrogen molecule, due to the d-wave nature of the lowest partial wave of the incident electron [15], and $l_1 = l_2 = l_3 = 1$ for NO, corresponding to a p-wave nature for the three resonant states [29]. In order to reproduce the position and width of the peaks in the experimental cross section, the constants $C_i$ in equation (8), for $\Gamma_i$, were considered as phenomenological external parameters of the model and empirically adjusted. Their values are given in table 2 for both

| Table 1. Morse parameters for $N_2$, $N_2^-$, NO and NO$^-$ potential states (equation (7)) and reduced mass $\mu$ for the neutral species. |

Figure 1. Morse potentials for (a) $N_2$ (solid line) and $N_2^-$ (dashed line); (b) NO (solid curve) and the three NO$^-$ states: $3\Sigma^-$ (short-dashed line), $1\Delta$ (dotted–dashed line) and $1\Sigma^+$ (long-dashed line).
processes (1) and (2). The shift operator $\Delta(R)$ in equation (5) has been included in the resonant potential [21]. The plots in figure 2 show the resonance widths for $N_2^+$ and NO$^-$, obtained using equation (8). In the case of NO$^-$, the calculated widths are compared with the $R$-matrix results, where the resonance position and width are calculated by fitting the eigenphase sum in the fixed-nuclei approximation with a Breit–Wigner profile [29]. To validate the numerical results, we changed the coefficients in table 2 by $\pm 10\%$ and noted that the effect on the cross sections due to this change is negligible, in particular for the $N_2$ case.

The discrete-continuum coupling matrix element $V_k(R)$ of equation (5) is written for the nitrogen molecule as [21]

$$V_k^2(R) = \frac{1}{2\pi} \frac{\Gamma(R)}{k(R)},$$

(9)

where $k(R)$ is given by

$$k^2(R) = \frac{2m}{\hbar^2} [V^-(R) - V_0(R)].$$

(10)

For the case of NO we have modulated $V_k(R)$, following [18], with the so-called penetration factor, an ad hoc function introduced to force the correct dependence of the cross section on the energy near the excitation threshold, namely,

$$f(k, R) = \begin{cases} k/k(R) & \text{if } k < k(R), \\ 1 & \text{otherwise.} \end{cases}$$

(11)

Table 2. Coefficients $C_i$, in equation (8), for $N_2^+$ and NO$^-$ resonant states.

<table>

The coupling matrix element for NO is thus written as

$$V_k^2(R) = f^{2i+1} \frac{1}{2\pi} \frac{\Gamma(R)}{k(R)},$$

(12)

Equation (4) can be related to differential cross section by the approximate expression:

$$\sigma_{il}(\epsilon_i) = \frac{1}{g_i(\theta)} \frac{d\sigma_{ii}(\Omega)}{d\Omega},$$

(13)

where the angular factor $g_i$, depending on the scattering angle $\theta$, is explicitly defined in [21]. In the following, for purposes of comparison, we will make use of this equation only to extract the integral cross section $\sigma_{il}(\epsilon_i)$ from the measured differential data.

In this paper we have computed the cross sections for the transitions $(v_i, J_i) \rightarrow (v_f, J_f)$ involving all the possible vibrational levels of $N_2$ and NO molecules and for all the diagonal rotational transitions $J_i = J_f = J$ with $0 \leq J \leq 150$.

3. Theoretical and experimental comparisons

In order to ascertain the accuracy of LCP calculations we compare our RVE cross section results for the $N_2$ and NO molecules with the theoretical and experimental cross sections and rate coefficients currently available in the literature.

3.1. $N_2$

The cross sections for process (1) are calculated by equation (4) where the degeneracy factors for $N_2^+(X^1\Sigma^+_g)$ and $N_2^+(^2\Pi_g)$ have been set to $g = 1$ and $g_t = 4$, respectively.

![Figure 2](image-url)

Figure 2. Resonance width obtained according to equation (8) for $N_2^+$ and for the three states of NO$^-$ as indicated in the figures. The points refer to the $R$-matrix calculation taken from [29].
Figure 3. Electron–N$_2$ theoretical–experimental cross section comparison for the rotationless $v_i = 0 \to v_f = 1, 5, 10$ transitions as indicated in the panels. Full lines: present calculations; dashed lines: experimental results of Allan [9].

Figure 4. Electron–N$_2$ theoretical–experimental cross section comparison for the rotationless $v_i = 0 \to v_f = 1, 2$ transitions as indicated in the panels. Full lines: present calculations; dashed lines: unpublished experimental results of Wong as cited in [13].

Figure 5. Electron–N$_2$ comparison of the present RVE calculations (full line) with the $R$-matrix results (dashed line) [14] for the rotationless transitions shown in the panels.

Figure 3 compares the cross sections for the rotationless $v_i = 0 \to v_f = 1, 5, 10$ transitions with the experimental data of Allan [9]. The comparison shows a very good agreement among the two sets of data for the first two transitions, while some discrepancy, around a factor of 2.8 at the main peak, is observed in figure 3(b) for the $0 \to 10$ excitation. In this last case, however, the absolute cross section values are relatively small, which can lead to significant uncertainties in the experimental values.

Figure 4 compares the theoretical RVE results with unpublished experimental measurements of Wong as reported in [13], for the rotationless vibrational transitions $0 \to 1, 2$. Our calculations are able to reproduce the experimental values of the number of peaks, their positions and peak values of cross sections quite accurately.

Figures 5(a) and (b) show a comparison of the present cross sections with those obtained with a non-adiabatic $R$-matrix approach [14] for the rotationless vibrational transitions $0 \to 3$ and $0 \to 4$, respectively. The relative position of the peaks in the two calculations is shifted for both the transitions. This discrepancy can be ascribed to the different input quantities used in the two calculations. The RVE cross sections, defined earlier, are in fact quite sensitive to variations of the potential curves and widths [30] and, as explained in section 2, we have adjusted our input parameters to reproduce the experimental data of Allan [9].
3.2. NO

For the RVE of the NO molecule, we have calculated the cross sections separately for each of the three processes \( ^2\Pi \rightarrow ^1\Sigma^+ \), \( ^2\Pi \rightarrow ^3\Sigma^- \) and \( ^2\Pi \rightarrow ^1\Delta \). The total cross section has then been obtained as a weighted sum of all the contributions, namely [18],

\[
\sigma_{v_i \rightarrow v_f}(\epsilon_i) = \frac{1}{8} \left[ \sigma_{^2\Pi \rightarrow ^1\Sigma^+}(\epsilon_i) + 3\sigma_{^2\Pi \rightarrow ^1\Sigma^-}(\epsilon_i) + 2\sigma_{^2\Pi \rightarrow ^1\Delta}(\epsilon_i) \right],
\]

where the coefficients are the statistical weights of each state [18]. Interference terms are neglected.

Figure 6 shows a comparison of our RVE cross sections for the \( 0 \rightarrow 0, 1, 2, 3 \) vibrational transitions with the differential cross sections measured by Allan [10] at an angle of 135° and multiplied, according to [18], by a factor of \( 4\pi \) to obtain, approximately, the integrated cross sections. The agreement is quite satisfactory considering the fact that we used these experimental results to optimize the input parameters for the adiabatic potentials and resonance widths of tables 1 and 2. No non-resonant background contribution has been included in the calculations. In fact, in figure 6(a) the discrepancy between our calculated \( 0 \rightarrow 0 \) elastic cross sections and the measurements of [10] is precisely due to the contribution of non-resonant background.

Figure 7 shows a comparison of our RVE cross sections with the non-local calculations of Trevisan et al [18] for the \( 0 \rightarrow 0, 1, 2, 3 \) vibrational transitions. The agreement here also is very satisfactory for all the transitions except for the elastic process, where the non-local cross sections are significantly higher than the local results. A discrepancy by a factor of 6 is in fact observed at the second peak with respect to the present calculations which, however, have been calibrated using the experimental data of Allan.

3.3. Rate coefficients

The rate coefficients for both processes (1) and (2) were calculated using equation (3) by assuming a Maxwellian electron energy distribution function. A comparison for \( \text{N}_2 + e \) system, with the well-known rate coefficients of Huo [16], is shown in figure 8 for the \( v_i = 0 \rightarrow v_f = 1, 2, 3, 4, 5 \) transitions up to an electronic temperature of \( T_e = 5 \) eV. The representative curves almost overlap, so the two calculations give in fact almost the same results for the transitions shown in the figure.

To the best of our knowledge, no rate coefficient data for the electron collision processes involving the NO molecule are available in the literature.

4. Results

As mentioned earlier, we calculated the cross sections and rate coefficients as a function of the electron energy and electron temperature, respectively, for all possible electron-impact-induced rovibrational transitions occurring according to processes (1) and (2). Since the database produced is prohibitively large to be completely shown in this paper, in this section we limit ourselves to the discussion of some particular cases. The whole database, however, will be provided in electronic form elsewhere (see section 5).
Figure 7. Electron–NO comparison of the present RVE calculations (full lines) with those of Trevisan et al [18] (dashed lines) for the vibrational transitions 0 → 0, 1, 2, 3.

Figure 8. Comparison of the present electron–N₂ RVE rate coefficients (full lines) with those of Huo et al [16] (dashed lines) as a function of the electron temperature. The curves refer to the transitions starting from vᵢ = 0 and ending on the final levels vᵢ = 1, 2, 3, 4, 5 as indicated in the figure.

The RVE cross sections for the inelastic rotationless transitions vᵢ = 0 → vᵢ = 1–5, 10 for N₂ are shown in figures 3–5. A general reduction in the magnitude of the main peaks is observed as the final level is increased. The same trend is exhibited by the curves of figures 9(a) and (b) where the elastic and vᵢ = 20 → vᵢ ≥ vᵢ cross sections, for selected levels vᵢ of N₂, are shown. The trend of the cross sections is reflected in the behavior of the rate coefficients, shown in figures 9(c) and (d) as a function of the electron temperature, for the same excitation processes as those shown in panels (a) and (b).

Analogous comments hold for figure 10 where the elastic and inelastic cross sections as well as rate coefficients for process (2), involving the NO molecule, are shown for the rotationless vibrational transitions indicated in the figures.

In view of the plasma modeling applications, we have also investigated the effect of the rotational excitation of molecule on cross sections and rates. Figures 11(a) and (b) show the cross sections for the two vibrational transitions 0 → 0 and 0 → 10, respectively, occurring through process (1) where now the nitrogen molecule is assumed to be initially as well as finally in different rotational levels (Jᵢ = Jᵢ = J). We have, in particular, considered the three cases where J = 0, 100 and 150. No significant variation is observed in the order of magnitude of the cross sections in going from J = 0 to J = 150. An enhancement of the main peaks, by about a factor of 2, is seen in fact for the vibrationally elastic process in figure 11(a), while a decreasing of the peak values occurs for the vibrationally inelastic transition in figure 11(b) as J is increased. A shift toward smaller energy is also observed, as expected, in both the excitations, coming from the lowering of the threshold caused by a reduction in the transition energy. Figures 12(a) and (b) show the same cross sections occurring through process (2) for the NO molecule. However, in this case the main peaks are reduced for vibrationally elastic process and enhanced for vibrationally inelastic process, with respect to J = 0, as the value of J is increased.

The rate coefficients for N₂ and NO, respectively, for different J values and for the elastic 0 → 0 and inelastic 0 → 10 vibrational transitions are shown in figures 11(c) and (d) and 12(c) and (d). Inspection of the figures for the elastic case shows that the rates are more sensitive to the rotational contribution for temperatures above 1 eV for nitrogen and
above 0.2 eV for nitric oxide. For $T_e < 1$ eV practically no rotational effects is observed in N$_2$, while for NO the rates become insensitive to the initial rotational excitation of the molecule for high $J$ and for $T_e < 0.2$ eV. For the inelastic case the situation is less clear, but no large variations, as $J$ changes, are observed in the whole range of temperatures investigated.

5. Summary

We presented in this paper the vibrational-excitation cross sections and rate coefficients for processes occurring through resonant electron impact on N$_2$ and NO molecules, for modeling purposes. Complete sets of data have been produced using
Figure 11. Cross sections and corresponding rate coefficients for (a), (c) 0 → 0 elastic and (b), (d) 0 → 10 inelastic vibrational transitions involving the N₂ molecule initially in different rotational levels: full line $J = 0$, dashed line $J = 100$, dotted line $J = 150$.

Figure 12. Same as figure 11 for the e–NO process.

the local complex potential model for the description of the nuclear dynamics, and by representing the required input electronic potential energies and widths by parametric standard expressions, appropriately adjusted to reproduce the experimental measurements. We also illustrated the calculation by commenting on some particular selected $v_i \rightarrow v_f$ transitions, and showing the effect of the initial rotational excitation of the target molecule on RVE cross sections and rates.

The entire cross section and rate coefficient database, including all the $v_i \rightarrow v_f$ transitions, and for $J$ ranging from 0 to 150, is available at the website: http://users.ba.cnr.it/imip/cscpal38/phys4entry/database.html
Acknowledgments

The authors wish to thank Dr A Laricchiuta (IMIP-CNR, Bari, Italy), Dr D Bruno (IMIP-CNR, Bari, Italy), Dr T N Rescigno (LBNL, Berkeley, USA) for helpful discussions, and Professor J Tennyson (UCL, London) for reading the manuscript.

This work has been performed under the auspices of the European Union Phys4Entry project funded under grant FP7-SPACE-2009-1 242311.
